2 ABSTRACT

3 Time of eating has been shown to be associated with diabetes and obesity but little is known
4 about less healthy foods and specific time of their intake over the 24 hours of the day. In this
5 study we aimed to identify potential relationships between foods and their eating time, and
6 see whether these associations may vary by diabetes status. The National Diet and Nutrition
7 Survey (NDNS) including 6802 adults (age ≥ 19 years old) collected 749,026 food recordings
8 by a 4-day-diary. The contingency table cross-classifying 60 food groups with 7 pre-defined
9 eating time slots (6-9am, 9am-12pm, 12-2pm, 2-5pm, 8-10pm, 10pm-6am) was analyzed by
10 Correspondence Analysis (CA). CA biplots displaying the associations were generated for all
11 adults and separately by diabetes status (self-reported, pre-diabetes, undiagnosed-diabetes, and
12 non-diabetics) to visually explore the associations between food groups and time of eating across
13 diabetes strata. For selected food groups, odds ratios (OR, 99% confidence intervals, CI) were
14 derived of consuming unhealthy foods at evening/night (8pm-6am) vs. earlier time in the day, by
15 logistic regression models with generalized estimating equations. The biplots suggested positive
16 associations between evening/night and consumption of puddings, regular soft drinks, sugar
17 confectioneries, chocolates, beers, ice cream, biscuits, and crisps for all adults in the UK. The OR
18 (99% CIs) of consuming these foods at evening/night were respectively 1.43 (1.06, 1.94), 1.72
19 (1.44, 2.05), 1.84 (1.31, 2.59), 3.08 (2.62, 3.62), 7.26 (5.91, 8.92), 2.45 (1.84, 3.25), 1.90 (1.68,
20 2.16), 1.49 (1.22, 1.82) vs. earlier time in the day adjusted for age, sex, body mass index, and
21 social-economic levels. Stratified biplots found that sweetened beverages, sugar-confectioneries
22 appeared more strongly associated with evening/night among un-diagnosed diabetics. Foods
23 consumed in the evening/night time tend to be highly processed, easily accessible, and rich in
24 added sugar or saturated fat. Individuals with undiagnosed diabetes are more likely to consume
25 unhealthy foods at night. Further longitudinal studies are required to ascertain the causal direction
26 of the association between late-eating and diabetes status.

28 diabetes

INTRODUCTION

29 The timing of energy intake has been shown to be associated with obesity and diabetes. (Almoosawi
30 *et al.*, 2016) Specifically, eating late at night or having a late dinner was found to be related to higher
31 risk of obesity (Xiao *et al.*, 2019; Yoshida *et al.*, 2018), hyperglycemia (Nakajima and Suwa, 2015),
32 metabolic syndrome (Kutsuma *et al.*, 2014), diabetes (Mattson *et al.*, 2014), and poorer glycemic control
33 among diabetics (Sakai *et al.*, 2017). However, the relationship between food choice and the time of
34 food consumption during the day is left largely unknown. Shiftworkers have an increased risk of obesity
35 (Balieiro *et al.*, 2014; Barbadoro *et al.*, 2013), and diabetes (Pan *et al.*, 2011), possibly due to limited
36 availability of healthy food choice during their night shifts (Bonnell *et al.*, 2017; Balieiro *et al.*, 2014).
37 Previous survey data from the UK National Diet and Nutrition Survey Rolling Programme (NDNS RP)
38 found that overall, 3.4% of men and 2.3% of women aged 19-64 had fasting glucose concentrations above
39 the clinical cut-off for diabetes (≥ 7 mmol/L). Moreover, the proportion of men with undiagnosed diabetes
40 increased with age to over 20% in the UK population (Almoosawi *et al.*, 2014). Identifying those unhealthy
41 foods that might be chosen during late night time would be helpful when guiding people to change their
42 eating habit for the purpose of either weight loss or glycemic control. Dietary diary recordings from NDNS
43 RP surveys can provide detailed food choice data for exploration of the relationships between food groups
44 and their time of consumption in the general population.

45 In this study, we aimed to describe the relationship between food groups and the time of day when they
46 were consumed, and how such relationships may vary by status of type 2 diabetes using the data published
47 by the NDNS RP from 2008 to 2017 as this survey includes diet diaries providing detailed information on
48 the time of day of food intake.

METHODS

49 6802 adults (2810 men and 3992 women) and 749026 food recordings collected by the NDNS RP 2008-17
50 were analyzed in the current study (MRC Elsie Widdowson Laboratory and NatCen Social Research, 2018).
51 The survey comprised a cross-section representative sample of the UK adult population taken over the
52 period 2008-2017. The sample was randomly drawn from a list of all addresses in the UK, clustered into
53 postcode sectors. Details of the rationale, design and methods of the survey can be found in the previously
54 published official study reports (Bates *et al.*, 2014; Roberts *et al.*, 2018). The NDNS-RP, funded by Public
55 Health England and the UK Food Standards Agency, is registered with the ISRCTN registry under study
56 ID ISRCTN17261407 and received ethical approval from the Oxfordshire Research Ethics Committee.

57 A four-day food diary method was used in the NDNS RP to collect the detailed food items and their time
58 of consumption from participants. Comparison between the food diary method and a repeated 24-hour
59 recall questionnaire was performed in a subset of study sample prior to the launch of the NDNS RP in
60 2008 and found that they were similar in terms of response rate as well as the ability to collect correct
61 nutrition intake data. And the four-day food diary method was adopted because it is considered to be more
62 flexible and adaptable to cover wide population age range in the survey. More details can be found in the
63 Appendix A of the official NDNS RP study report (Bates *et al.*, 2014; Roberts *et al.*, 2018). Furthermore,
64 the same food diary methods is actually used in large studies conducted in the UK, such as the the MRC
65 National Survey of Health and Development (NSHD) (1946 British Birth Cohort) (Price *et al.*, 1997), the
66 EPIC Norfolk Study (Bingham *et al.*, 2001), the UK Women's Cohort Study in Leeds (Cade *et al.*, 2004),

and the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort (Glynn *et al.*, 2005). Another validation study of the food records against double-labelled water has also been undertaken among a subset of NDNS participants. Full results of the analysis have been reported in Appendix X of the official survey report (Lennox *et al.*).

In the food diary recordings, time of the day was categorized into 7 slots: 6-9 am, 9-12 noon, 12-2 pm, 2-5 pm, 5-8 pm, 8-10 pm and 10 pm - 6 am. Foods recorded were classified into 60 standard food groups with 1 to 10 subgroups each: the details are given in Appendix R of the NDNS official report (NatCen Social Research, MRC Elsie Widdowson Laboratory, Univeristy College London. Medical School., 2018). We focused on the 60 standard food groups in the current analysis. Diabetes status was defined as: 1) healthy if fasting glucose was lower than 6.10 (mmol/L), hemoglobin A1c (HbA1c) was less than 6.5 (%), and without self-reported diabetes and treatment for diabetes ($n = 2626$); 2) pre-diabetic if fasting glucose was lower between 6.10 and 6.99 (mmol/L, inclusive) but without self-reported diabetes and without treatment for diabetes ($n = 133$); 3) undiagnosed diabetic if either fasting glucose was higher or equal to 7.00 (mmol/L) or HbA1c higher or equal to 6.5 (%) but without self-reported diabetes and treatment for diabetes ($n = 99$); 4) diabetic if participant had self-reported diabetes or was under treatment for diabetes ($n = 227$). Consequently, there was also a large number of adults (3717 adults of whom 1519 men and 2198 women) whose diabetes status did not fall in one of above categories and could not thus be confirmed; these were retained in the whole sample (unstratified) analyses. In addition, the National Statistics Socio-economic Classification (Rose and Pevalin, 2005) was applied in the survey and accordingly, the socio-economic status of participants was classified in one of 8 categories.

Correspondence analysis (CA) (Greenacre, 2017; Chapman *et al.*, 2017; Palla *et al.*, 2020) was used as a tool for data mining, visualization and hypotheses generation using half of the randomly selected NDNS diary entries data. Specifically, the contingency table generated by cross-tabulating 60 food groups and 7 time slots were analyzed by CA. Through CA, the 60 categories of standard foods and the 7 time slots were projected on biplots, i.e. onto two dimensional plots that could jointly contain large percentage of the χ^2 deviation (or inertia) of the contingency table. Biplots that graphically show the association between time of day and food groups were derived for all adults and separately according to their diabetes status. CA is a statistical technique to explore relationships between categorical variables in a two-dimensional contingency table.

In the current analysis context, CA was used as a tool to visually depict the relationship between food groups and time of consumption. CA was the technique to flag up those food groups that have a similar or different “profile” across time categories or, symmetrically, those times of day that have a similar or different “profile” across food groups. In particular “profile” indicates the relative frequency of the consumption of one food across different time in the day (or, symmetrically, the relative frequency of consumption of different foods at one specific time period) and what CA measures are its departure from the average food (or time of day) profile. One simple example is that if about 77.8% of all foods were consumed during the daytime (earlier than 8 pm), but only 23.5% of beer consumption were recorded during the daytime, then we say beer has a “profile” different from the average food profile with respect to time of day of consumption and, in particular, beer is associated to evening/night consumption. CA can produce biplots to visually show the χ^2 deviation of food (and time) profiles from the average profile which is called “inertia.” These biplots use the first two most informative dimensions to show the inertia of the contingency table. The horizontal axis of the biplot represents the direction along which the contingency table rows and columns show their greatest deviations from the average row or column profile. The vertical axis represents the direction, perpendicular to the first, having the second-largest deviations. There are two

percentage labels for each axis which indicate how much of the total inertia were explained along that axis. The sum of the two percentages is lower than 100%, the remaining inertia cannot be shown when reducing to 2 dimensions if there are more than 3 foods or time-slots. The origin in each biplot is the average profile of all points in the plot, while the length of the vector from the origin to each profile point represents its deviation from the average profile. The distance between row (food) and column (time slots) profile points and the direction in which they lie away from the origin is indicating how they are associated with each other. The potential association is greater if 1) points are located in similar directions away from the origin and 2) the farther they are from the origin.

To account for the hierarchical structure of the data (food recorded by the same individuals who lived within the same area/sampling units) and to calculate population average odds ratios (OR), logistic regression models with generalized estimating equations (GEE) were subsequently used to test the associations that were first suggested by visual inspection of biplots generated by CA, using the remaining half of the diary entries data. The marginal ORs and their 99% confidence intervals (CI) were derived of consuming unhealthy food groups (selected by CA) later in the day (8 pm - 6 am, i.e. in the evening and night) compared to earlier in the day (in the morning or afternoon). CA and biplots were conducted and generated by the following packages under R environment (R Core Team, 2019): FactoMineR, factoextra, ggplot2, ggrepel (Lê et al., 2008; Kassambara and Mundt, 2019; Wickham, 2016; Slowikowski, 2019) Logistic regression models with GEE were performed with SAS procedure GENMOD (SAS Institute, 2013) adjusted for age, sex, body mass index (BMI) and socio-economic levels, which were deemed the main potential confounders of the associations.

RESULTS

The dataset consisted of 2810 (41.3%) men and 3992 (58.7%) women aged older than or equal to 19 years old with the mean age of 49.9 years (standard deviation, SD = 17.6). Of these individuals 22.6 % were current smokers, 24.3 % were past smokers. The average body mass index (BMI) was 27.7 kg/m² (SD = 5.41). Among the food recordings collected (n = 749026), 56.9% were recorded during traditional breakfast (6 am - 9 am: 14.3%), lunch (12 noon - 2 pm: 18.5%), or dinner (5 pm - 8 pm: 24.1%) time slots, more details can be found in Supplementary Table S1. Table 1. shows the top 37 food groups that contributed to 90% of the total calories consumed by adults in NDNS RP. These food groups accounted for 478028 of the total diary entries (63.8 %). The random process split the whole set of food recordings into a hypothesis generating dataset of 374682 and a testing dataset of 374344 entries.

Figure 1-5 present the CA biplots that visually summarize the associations between 60 food groups and the time of their consumption in the entire sample and then stratifying by their diabetes status. In Figure 1, the horizontal axis explains 68.9 % of the association structure (inertia) between food and time while the vertical axis reflects 15.3 % of the same relationship. Therefore, a total of 84.2 % of the inertia between food and time were captured in this figure which shows a visual summary of how those two categorical variables are related. Specifically, time slots later than 8 pm are shown in the upper side of the plot closer to alcoholic products or highly processed/energy-dense foods (sugar confectioneries, chocolates, biscuits, regular softdrinks, ice cream, crisps); times earlier than noon appear in the left hand side together with typical breakfast foods (cereals, milk, bread, etc.).

To visualize the potentially different associational patterns between food groups choice and time slots according to diabetes status, Figure 2-5 display the CA biplots in subsets of the data. Depending on different diabetes status, these biplots explained between 76.3% and 84.1% of the inertia in the data. Similarly to the biplot created from the total sample (Figure 1), later time in the day (8 pm and later) are shown

in the upper side of each figure and suggested an association with the alcoholic beverages and highly processed or energy-dense food groups. Additionally, some food groups and time slots also flagged up associations potentially different by diabetes status. For example, puddings seemed to be closer to later time in the day among undiagnosed diabetics (Figure 4) while for diagnosed diabetic patients (Figure 3) they were closer to traditional dinner time (5 pm to 8 pm) or earlier in the day. Furthermore, sugar confectioneries/chocolates/biscuits/regular soft drinks appeared to be associated with later time in the day (8 pm or later) more strongly among undiagnosed diabetics (Figure 4) than the other participants.

Based on the findings suggested from Figure 1-5, we decided to focus on puddings, regular soft drinks, confectioneries, chocolates, beers, ice cream, biscuits, crisps as these foods either showed a particularly strong association with time of the day or a different pattern of association across different strata of the survey sample; hence, we tested the following null hypotheses using logistic regression models (adjusted for age, sex, and socio-economic levels) with GEE: that the odds of consuming each selected food at later time of the day (8 pm - 6 am) is the same compared to earlier in the day; and the associations of the above-mentioned food groups and time slots are the same among participants with different diabetes status (i.e. no interaction between the time of food intake and diabetes status). The results are summarized in Table 2.

The listed food groups were found to have higher odds to be consumed between 8 pm and 6 am with higher odds compared to earlier time. The OR (99% CIs) main effects of consuming these foods at evening/night were for puddings 1.43 (1.06, 1.94), for regular soft drinks 1.72 (1.44, 2.05), for sugar confectioneries 1.84 (1.38, 2.69), for chocolates 3.08 (2.62, 3.62), for beers 7.26 (5.91, 8.92), for ice cream 2.45 (1.84, 3.25), for biscuits 1.90 (1.68, 2.16), for crisps 1.49 (1.22, 1.82) vs. earlier time. Opposite directions of the association for puddings were detected across diabetes status: the ORs (99% CIs) of consuming puddings at night time (8 pm or later) compared to earlier time were 1.55 (1.13, 2.15), 0.95 (0.17, 5.20), 1.82 (0.41, 8.03), and 0.63 (0.15, 2.66) for healthy, prediabetic, undiagnosed diabetic, and diabetic participants, respectively. Furthermore, undiagnosed diabetic patients were found to have particularly high odds of consuming regular soft drinks (OR: 2.82; 99% CI: 1.24, 6.43), and sugar confectioneries (OR: 10.61; 99%CI: 2.35, 47.04) during night time periods compared to participants with other diabetes status.

DISCUSSION

The present study described the potential relationships between food groups and time of their consumption in a representative sample from the NDNS RP. Many unhealthy foods emerged from CA were found to be more likely to be consumed after 8 pm. These included alcoholic/sweetened beverages, chocolates and other foods rich in added sugars and saturated fats such as biscuits and ice cream. Foods chosen in the evening/night time slots tend to be highly processed and easily accessible. Specifically, undiagnosed patients might be at a higher risk of worsening their condition as they were found to have higher odds to choose a number of less healthy foods after 8 pm (sugar confectioneries, regular soft drinks) than diabetics and non-diabetics. Those foods might need to be targeted when designing intervention to those who might be at risk of being diabetics.

These findings are concerning considering previous research have indicated that quality of macronutrient intake in the evening is likely to influence fasting glucose levels and glycaemic response to subsequent meals in the morning. (Wolever *et al.*, 1988) One prospective study reported women who ate later than 9pm had 1.51 times (95% CI 1.16 to 1.93) higher 5-year risk of developing prediabetes/diabetes than those having their time of last eating episode between 4 to 9pm. (Faerch *et al.*, 2019) More recently, a randomized controlled trial indicated that consuming carbohydrates at dinner irrespective of glycaemic index raised

195 postprandial glucose response to breakfast producing what is known as a second meal effect (Haldar et al.,
196 2020). Similar observation have been made by Nitta and colleagues who observed that eating sweet snacks
197 post-dinner worsened glycaemic excursions in the evening and at subsequent breakfast (Nitta et al., 2019).
198 Added to this is evidence that suggests that the late-night dinners induce post-prandial hyperglycemia in
199 patients with type 2 diabetes and that interventions at this eating occasions can result in a profound impact
200 on post-prandial glycaemia. On the balance of this evidence, targeting and improving the timing and quality
201 of foods in evening eating occasions provides a unique opportunity to design intervention to those who
202 might be at risk of being diabetics.

203 A compelling finding of our study is the observation that diabetes patients were found to be potentially
204 controlling their choice of food groups such as avoiding puddings at night. However, higher odds of
205 consuming alcoholic beverages and energy condensed foods such as chocolates and sugar confectioneries
206 at night among individuals with diabetes suggests that their food choice might need further modifications.
207 Food intake late in the night is in misalignment with the circadian rhythm of the insulin response, which
208 may cause greater glycaemic exposure and elevated HbA1c levels even for healthy individuals (Faerch
209 et al., 2019). Disrupted timing of food intake, overeating in the evening, unhealthy food chosen at later
210 time in the day can result in poor glucose control and increase the likelihood of diabetic complications
211 (Nakajima and Suwa, 2015; Sato et al., 2011; Kadowaki et al., 2018; Reutrakul et al., 2014). Assessing
212 the relationships between food groups and timing of eating by diabetes status can be considered as a first
213 step towards identifying specific public health targets for behavior change/intervention. This is important
214 as most current public health strategies and dietary recommendations do not provide targeted advice
215 that takes into considerations specific eating occasions while targeted advice is more likely to result in
216 sustainable behavioural change. Our findings are consistent with previous evidence that has found that both
217 sweetened and alcoholic beverages are responsible for large portion of energy consumption at night in
218 other populations (Hassen et al., 2018).

219 However, an important limitation in this study is the cross-sectional study design. Our findings do not
220 implicate whether it would be better to consume sweets or desserts later or earlier in the day, which should
221 be clarified in intervention designed studies in the future. Some findings, such as beers turn to be more
222 consumed at night, are already known and may not be surprising. However, the fact that some of the
223 unhealthy food were more likely to be consumed at night and even more frequently among undiagnosed
224 diabetic participants is alarming. Moreover, The inability to assess the temporal relationship between
225 timing of food intake and diabetes status means that a cause-effect relationship between time of unhealthy
226 food intake and diabetes status cannot be established. Hence, further prospective studies are warranted to
227 investigate the causal relationship between diabetes and both quality and timing of eating. Moreover, the
228 current study assumes that mis-reporting occurred equally amongst all eating occasions. This limitation has
229 been reported by previous literature as an important methodological limitation of chrononutrition (Fayet-
230 Moore et al., 2017); in fact further investigation would be warranted to assess the effect of differential
231 misreporting on epidemiological studies in chrono-nutrition in order to suggest possible corrections, e.g. for
232 differential under-reporting at different times of the day (e.g. main meals vs. snack times). Finally, we
233 did not include variables indicating abdominal obesity and sedentary lifestyle such as physical activity or
234 waist circumference in the second step of the current analysis mainly due to missingness of the variables.
235 The associations comparing food consumed later vs. earlier time in the day presented here may be partly
236 explained or mediated through low level of physical activity and/or abdominal obesity especially among
237 those who were unaware that they have diabetes (un-diagnosed diabetes), further detailed investigation is
238 needed.

CONCLUSION

239 In summary, our study indicates that foods consumed in the evening/night time tend to be highly processed,
240 easily accessible, and rich in added sugar or saturated fat, whatever the diabetic status. Individuals with
241 undiagnosed diabetes are more likely to consume specific unhealthy foods at night. The survey cross-
242 sectional nature warrants further investigations by longitudinal cohort studies to establish the causal relation
243 between time of eating of unhealthy foods and diabetes.

NDNS RP: National Diet and Nutrition Survey Rolling Programme.

Table 2. Odds ratio (99% confidence intervals) for food groups eaten at night (8 pm - 6 am) vs. earlier time in the day, among total and according to different diabetes status, NDNS RP 2008-2017.

Selected food group	Overall	Healthy	Pre-diabetics	Undiagnosed diabetics	Diabetics
Pudding	1.43 (1.06, 1.94)	1.55 (1.13, 2.15)	0.95 (0.17, 5.20)	1.82 (0.41, 8.03)	0.63 (0.15, 2.66)
Regular soft drink	1.72 (1.44, 2.05)	1.70 (1.41, 2.05)	1.78 (0.90, 3.48)	2.82 (1.24, 6.43)	1.36 (0.59, 3.10)
Sugar confectionery	1.84 (1.31, 2.59)	1.55 (1.08, 2.23)	2.13 (0.34, 13.24)	10.51 (2.35, 47.04)	5.94 (1.86, 19.00)
Chocolate	3.08 (2.62, 3.62)	2.98 (2.51, 3.54)	4.06 (1.98, 8.31)	2.41 (0.88, 6.60)	4.92 (2.38, 10.20)
Beer	7.26 (5.91, 8.92)	7.55 (6.04, 9.43)	4.42 (2.19, 8.95)	8.29 (3.70, 18.56)	5.82 (2.03, 16.68)
Ice cream	2.45 (1.84, 3.25)	2.52 (1.86, 3.41)	3.39 (0.77, 14.89)	1.07 (0.15, 7.77)	1.74 (0.57, 5.32)
Biscuit	1.90 (1.68, 2.16)	1.78 (1.55, 2.05)	3.25 (1.99, 5.28)	2.96 (1.43, 6.10)	2.33 (1.45, 3.77)
Crisp	1.49 (1.22, 1.82)	1.49 (1.21, 1.85)	2.21 (0.90, 5.41)	1.59 (0.43, 5.95)	0.89 (0.34, 2.33)

Logistic regression models with GEE were adjusted for age, sex, body mass index, and social-economic levels.
